GENERATING NEW SHIP LINES FROM A PARENT HULL USING SECTION AREA CURVE VARIATION

Robert McNaull Computer Specialist Maritime Administration Washington, D.C.

- Mr. McNaull is currently responsible for computer aided preliminary ship design and analysis, finite element analysis of ship structures, and computer program development.
- Mr. McNaull holds a degree in ocean engineering from Florida Atlantic University, and in naval architecture from the University of California. He is working toward a doctorate in structural engineering from George Washington University.

1. ABSTRACT

Section area curve variation may be used to obtain a new set of fair ship lines from a parent hull by varying any or all of the following parameters: prismatic coefficient, longitudinal center of buoyancy, extent of parallel midbody, or slopes at entrance and run. A standard series may be obtained by varying any one of these parameters independently while holding the other parameters constant. Deriving a new set of ship lines using this approach has an advantage over other methods since a known parent hull with good stability, resistance, seakeeping, etc, qualities may be selected as the starting point for the new design.

In this paper a linear system of 10 simultaneous equations is presented which allows the independent variation of three of the parameters: prismatic coefficient, longitudinal center of buoyancy, and extent of parallel midbody on a parent section area curve. Another linear system of 12 simultaneous equations is presented which allows the independent variation of the above three parameters and the slopes at the entrance and run of a parent section area surve. A new set of ship lines can be obtained directly from the new section area curve. Matrix methods are used to solve the systems of equations. Several examples with numeric and graphic results from a computer program developed at the Maritime Administration are presented.

2. INTRODUCTION

There are several methods used today for creation of ship lines by computer. For example, ship lines can be derived from one of the following:

- a) a single parent hull (lines distortion approach)
- b) a series of parent hulls (standard series approach)
- c) geometrical hull form parameters (form parameter approach)

In the lines distortion approach new lines are obtained from the lines of one parent hull by modifying some form parameters, e.g. prismatic coefficient, longitudinal center of buoyancy, parallel midbody, etc. The advantage here is that known parent hull with good stability, resistance, and seakeeping qualities may be selected as the starting point for the new design. Lackenby [1]* developed a systematic mathematical approach to lines distortion of section area curves. Soding [2] developed transformation functions to distort section area curves, bilge radii, u-or-v shapes, stem and stern contours, etc.

Using the standard series approach, the derived hull form can be obtained by simply interpolating within the designs of that series. It is interesting to note that a standard series can be derived from a single parent or several parent designs by systematic variation methods such as lines distortion. (For example, the hulls of the British BSRA series were generated from several parent hulls using the lines distortion approach developed in [1].) The parent designs and the deduced variations are model tested and then documented with the published standard series in terms of offsets, lines, curves of form, and resistance and propulsive data. Some of the standard series are: Japanese, British, and Swedish tanker and cargo series, German HSVA series, Taylor series, Series 60.

^{*} Numbers in brackets designate References at end of paper.

In contrast to the lines distortion approach and the standard series approach, the form parameter approach does not require parent hulls. The new lines are created mathematically according to specified values of the parameters that define the significant curves of the new hull form Of the three approaches, the form parameter approach allows the greatest range of form variation and consequently requires a very experienced designer. Further discussion of use of form parameters can be found in the paper by Nowacki [3J.

Depending on which approach is used to generate the derived hull form, the resistance will be known to varying degrees. In the standard series approach, resistance information can be interpolated from the tabulated series resistance data, so the resistance of the derived hull is known. In the lines distortion approach, the resistance of the parent is known, so that of the derived hull can be expected to be very similar since only moderate modifications to the parent are allowed with this method. (It should be noted that while the resistance will be similar, there is no guarantee that the new hull will produce better">better hydrodynamic behavior than the parent.) In the form parameter approach the resistance is not known.

The following presentation is concerned only with the lines distortion approach. In particular, the section area curve variation method developed in reference [1] is modified and extended. The objective is to systematically distort the section area curve of the parent hull using a mathematical approach such that the new section area curve - and therefore the new hull form - will have the desired characteristics.

3. THE LINES DISTORTION APPROACH- SECTION AREA CURVE VARIATION

Several authors have addressed section area curve variation, but one of the most complete papers was presented in 1950 by Lackenby [1]. He derived the equations for the independent variation of three parameters of the section area curve: prismatic coefficient (Cp), longitudinal center of buoyance (LCB), and extent of parallel midbody. Any or all of the three parameters could be varied independently holding the other parameters constant. For example, LCB could be varied holding CP and extent of parallel midbody constant. This represented a significant improvement over such traditional methods as "swinging" the section area curve to shift the LCB. With the traditional methods, there is no control over the position of parallel midbody or position of maximum section; they are shifted forward or aft with the new LCB. Additionally, the prismatic coefficient is changed slightly.

To develop the equations for section area curve variation, a figure with some definitions will prove useful. If areas of transverse sections at stations along the length of the ship are calculated up to the design waterline and then plotted, the resulting curve is called the section area curve. See Figure 1. It has the following properties:

a) The area under the curve is-equal to the underwater volume, ', of the ship at the design waterline, DWL.

b) The first moment of the area is equal to the longitudinal center of buoyancy, LCB.

c) The non-dimensional Tred area under the curve is the prismatic. coefficient. Alternately, the maximum section area, AM, when multiplied by the ship length, SAC, gives a prison volume; this volume divided into the actual ship volume, y, is the prismatic coefficient, Cp.

Ship Profile

T = draft

DWL = design waterline

¥ = midships

FP = forward perpendicular AP = aft perpendicular

Section Area Curve

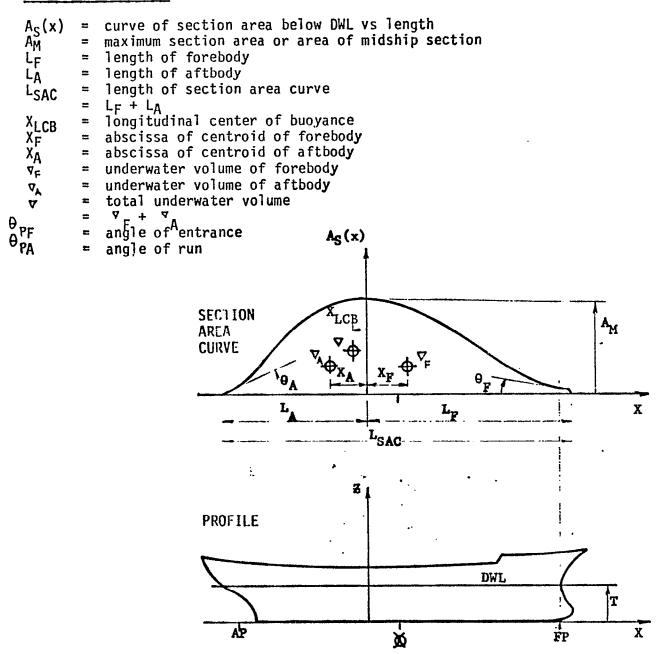

FIGURE 1. Section Area Curve Without Parallel Midbody

Note that the equations for section area curve variation apply equally well to waterlines. Only the terminology changes:

Section Area Curve Waterlines

Areas ; underwater volume, V waterplane area

Moments: longitudinal center of longitudinal center of flotation,

buoyancy, LCB L

Non-dimensional prismatic coefficient, C_p waterplane coefficient

areas:

The system of equations developed in [1] have three important limitations. The first being that length of forebody must be the same as length of aftbody. This is a result of the assumptions that the boundary between forebody and aftbody is exactly midships and that the stations forward of the forward perpendicular could be neglected. See Figure 2.

These assumptions cannot be made with the bulbous bows of today where the bulb volume is a non-negligible quantity, and with high speed cargo ships which have no parallel midbody and the station of maximum area is aft of midships. So the equations are rederived for a dimensional section area curve where length of forebody and aftbody may differ (as in Figure 1.).

The second limitation is that the original system of equations was solved by successive substitution. This obscures the presentation and makes the addition of new boundary conditions extremely difficult. A more general approach is to formulate the equations in matrices and use a direct numerical method like Gaussian elimination for the solution. A matrix approach greatly facilitates including additional boundary conditions in the system of equations, as will be done in what follows.

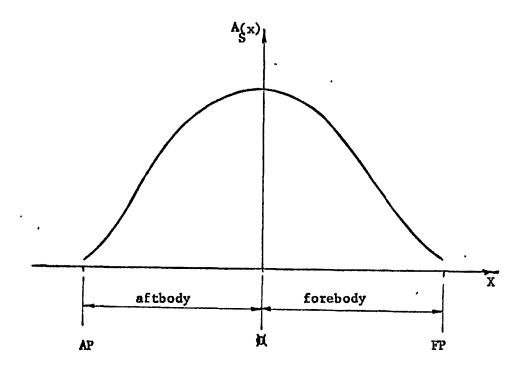

FIGURE 2. Sectio- Area Curve with Equal Forebody and Aftbody Lengths

A third limitation is that the equation for the longitudinal shifts of stations on the parent section area curve is not in general form. The equation for longitudinal shifts of stations determines how the original stations on the parent section area curveare shifted longitudinally to produce the derived section area curve with the desired characteristics. When the equation for longitudinal shifts has been calculated, the original offset stations are also shifted according to that equation to produce the new offset stations; the heights and half-breadths remain constant and only the stations are changed. The 8x value a point on the parent section area curve is shifted longitudinally is plotted vertically in the curve of longitudinal shifts in Figure 3.

In this paper the curves of longitudinal shifts of stations are second or third order equations. 1 There is one equation for the longitudinal shifts in the forebody and another equation for longitudinal shifts in the aftbody. Note in the example in Figure 3 that forebody stations on the parent section area curve are shifts forward (positive shifts) while aftbody stations on the parent section area curve are shifted forward (negative shifts).

As mentioned previously, the equation for longitudinal shifts of stations determines how the original stations on the parent section area curve are shifted longitudinally to produce a derived section area curve with the desired characteristics. So the objective is to calculate the coefficients of the equation for longitudinal shifts in the forebody and aftbody, We shall now present two systems of equations whose solutions are the coefficients of the equations of the longitudinal shifts. The first system of 10 linear simultaneous

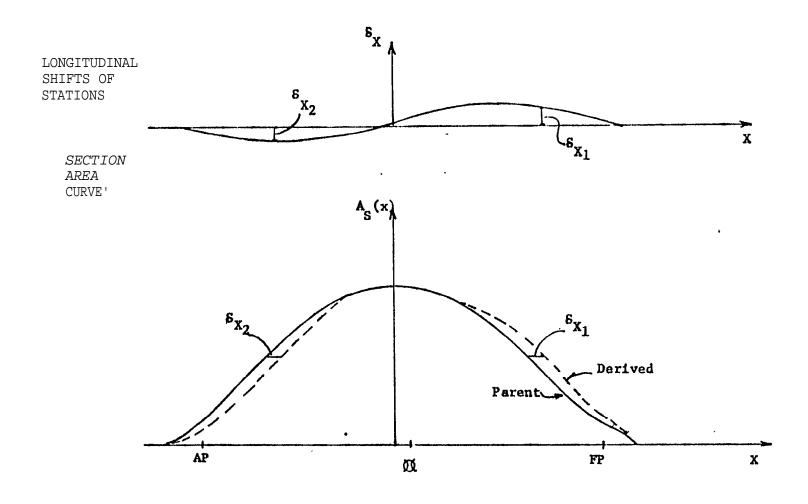

FIGURE 3. Longitudinal Shifts of Stations with Corresponding Derived Section Area Curve

equations allows the independent variation of three section area curve parameters: prismatic coefficient, longitudinal center of buoyancy, and extent of parallel midbody. In this case the equations of longitudinal shifts of stations are second order or parabolic. This is essentially the system of equations in [1] but with modifications to overcome the three mentioned limitations. The second system of 12 linear simultaneous equations allows the independent variation of prismatic coefficient, longitudinal center of buoyancy, extent of parallel midbody, and the slopes at the entrance and run. This is an extension of the system of 10 equations. Here the equations of longitudinal shifts of stations are third order or cubic.

4. EQUATIONS FOR PARABOLIC LONGITUDINAL SHIFTS

Four equations result from considering the forebody, four equations for the aftbody, and two equations for the combined forebody and aftbody; hence a system of ten linear simultaneous equations. The equations for the aftbody are identical in form to the four equations for the forebody, but the unknown coefficients are different and the X axis is reversed. The lengths of forebody and aftbody are not restricted to being equal.

4a. FOREBODY ONLY

In Figure 4 the solid curve abc represents the forebody of the parent section area curve. The x-axis units are length and the y-axis units are area. The dashed curve ab'c represents the forebody of the derived section area curve. At a position x the parent curve abc is shifted longitudinally by an amount 8x to produce curve ab'c.

Parent Forebody Curve (abc)

SF = abscissa Of centroid Of 8v F change in parallel midbody

 ${}^{8}_{8}$ xPF = longitudinal shift of station at x ${}^{9}_{DF}$ = slope of entrance of derived forebody

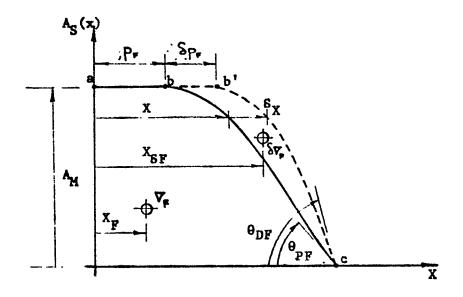

FIGURE 4. Forebody Section Area Curve

In order for the derived section area curve to have the desired prismatic coefficient, longitudinal center of buoyancy, and extent of parallel midbody, a second order expression of the following form is used for the longitudinal shifts in [1]:

(1)
$$8x = A(1-x) (x+B)$$

where 8x is the necessary longitudinal shift at each position x along the forebody and A and B are coefficients to be determined from the boundary conditions. Note that the term (1-x) includes the boundary condition that 8x be zero at the forward end of the curve i, e., at x=1 for a non-dimensionalized forebody length.

Instead of equation (1) we shall use a more general second order expression to simplify the algebra:

(2)
$$8 \times Ax^2 + Bx + c$$

where A, B, and C are constants to be determined from the boundary conditions.

Four equations for the forebody result from the following conditions:

(3) at
$$x = P_F$$
, $8x = 8_{pF}$ $8x = 8_{pF} = A_{pF}^2 + B_{pF} + C$

(4) at
$$x = L_{F}' 8x = 0$$
 $8x = 0 = AL_{F}^{2} + BL_{F} + C$

(3) at
$$x = P_F$$
, $8x = 8_{pF}$ $8x = 8_{pF} = A_{pF}^2 + B_{pF} + C$
(4) at $x = L_F'$ $8x = 0$ $8x = 0 = AL_F^2 + BL_F + C$
(5) $8\nabla_F = \int_{-\infty}^{A_{m}} 8x dA_S$ $8\nabla_F = 2A \nabla_F X_F + B \nabla_F + CA_M$

(6)
$$X_{SF}S\nabla_{F} = \int_{0}^{A_{m}} xSxdA_{c}$$
 $X_{SF}S\nabla_{F} = 3A\nabla_{F}K^{2}_{F} + 2B\nabla_{F}x_{F} + C\nabla_{F}$

where in equation (6) K_F is the radius of gyration about the A_S axis. There are five unknowns: A, B, C, $\delta \nabla_F$, and X_{SF} .

All other quantities can be determined

from the geometry of the forebody.

For the aftbody there are four more equations similar to (3), (4), (5), and (6) but with the coefficients A, B, C changed to D, E, F, respectively, and with subscript F replaced by A. In this case the five unknowns are D, E, F, $\&\nabla_A$, and $\&\nabla_{\&A}$.

4b. COMBINED FOREBODY AND AFTBODY

The total section area curve will now be considered to develop the remaining two equations. Figure 5 shows the total section area curve with the various parameters labeled. The solid curve is the parent and the dashed curve is the derived.

Two equations for the total section area curve result from the following conditions:

(7)
$$(\nabla + \delta \nabla) (X_{LCB} + \delta X_{LCB}) = \nabla X_{LCB} + \delta \nabla F X_{SF} - \delta \nabla_A \times \delta A$$

The total change must equal the change forward plus the change aft.

$$(8) \quad \mathbf{S} \nabla = \mathbf{S} \nabla_{\mathbf{F}} + \mathbf{S} \nabla_{\mathbf{A}}$$

With equations (3), (4), (5), (6) for the forebody and four more equations similar to (3), (4), (5), (6) for the aftbody, and equations (7) and (8) for the total section area curve, we have a system of ten equations in ten unknowns. The equations are written in matrix form in Figure 6. The ten unknowns are contained in the column vector at the right. The matrix and the column vector at the left contain all known quantities. A direct numerical method like Gaussian elimination can be used for the solution. Once the coefficients A, B, C and D, E, F are calculated, the longitudinal shifts in the forebody are known

Parent Section Area Curve

Derived Section Area Curve

change in underwater volume 84 ്+ &⊽ δV F change in volume of forebody δV A change in volume of aftbody **EXLCB** change in longitudinal center of buoyancy change in parallel midbody in forebody change in parallel midbody in aftbody SpF δ_{PA} **ODF** slope of entrance of derived forebody slope of run of derived aftbody 9_{DA}

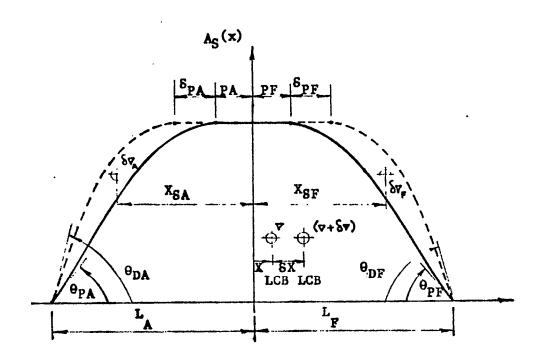

FIGURE 5. Total Section Area Curve

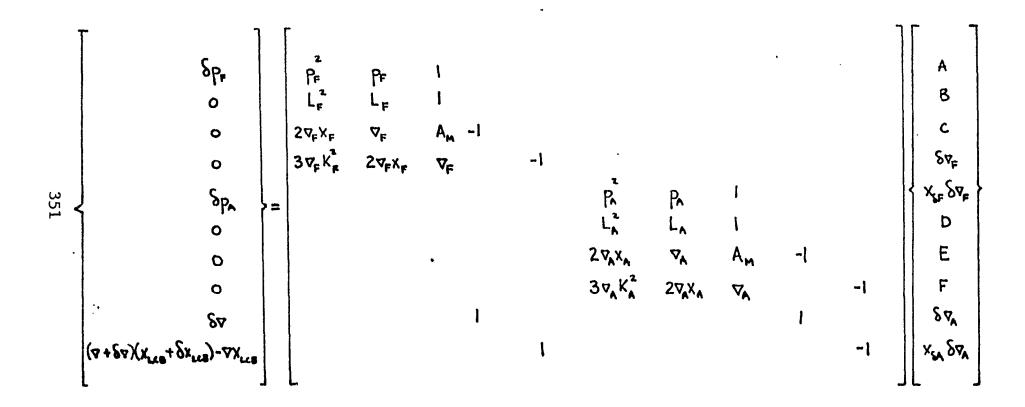

FIGURE 6. Ten Linear Simultaneous Equations for Parabolic Longitudinal Shifts

$$(9) \qquad \delta X_{\mathbf{r}} = Ax^{2} + Bx + C$$

and the longitudinal shifts in the aftbody are known

(10)
$$8X_X + Dx^2 + Ex + F$$

When points on the parent section area curve are shifted longitudinally according to equations (9) and (10), the resulting section area curve will have the derived prismatic coefficient, longitudinal center of buoyancy, and extent of parallel midbody. When stations in the offsets are shifted longitudinally according to equations (9) and (10), a derived hull form will result which has these characteristics.

5. EQUATIONS FOR CUBIC LONGITUDINAL SHIFTS

In this case five equations result from considering the forebody, five equations from the aftbody, and two equations from the combined forebody and aftbody; hence a system of twelve linear simultaneous equations. Again the aftbody and forebody equations are identical in form $\,$, but with different coefficients and different x-axis.

5a• FOREBODY ONLY

Figure 4 again applies, but the equation for longitudinal shifts becomes a third order expression.

(11)
$$\delta X = Ax^3 + Bx^2 + Cx + D$$

Where A, B, C, D, are constants to be determined from the boundary conditions. The forth constant is required since there is an added boundary condition; the slope at the end of the curve is specified.

Five equations for the forebody result from the following conditions:

(12) at
$$x = L_F$$
, $\frac{dy}{dx}$ = specified value $\tan \theta_{PF} \cot \theta_{DF} - 1 = 3AL_F^2 + 2BL_F + C$

(13) at
$$x = P_F$$
, $\delta x = \delta P_F$ $\delta x = \delta P_F = A P_F^3 + B P_F^2 + C P_F + D$

(14) at
$$x = L_F$$
, $\delta x = 0$ $\delta x = 0 = AL_F^3 + BL_F^2 + CL_F + D$

(15)
$$\delta \nabla_F = \int_{-\infty}^{A_m} \delta x dA_s$$
 $\delta \nabla_F = 3A\nabla_F k_F^2 + 2B\nabla_F x_F + C\nabla_F + DA_M$

(16)
$$X_{SF} S \nabla_F = \int_{a}^{A_{m}} x S x dA_{S}$$
 $X_{SF} S \nabla_F = 4A \nabla_F R_F^3 + 3B \nabla_F K_F^2 + 2C \nabla_F X_F + D \nabla_F R_F^3$

where in equation (12) $\tan \theta_{pF}$ is the slope of the parent curve at $X = L_F$ (which is known) and $\cot g_{DF}$ is the inverse of the slope of the derived curve at $X = L_F$ (which is specified) and where in equations (15) and (16) K_F is the radius of gyration (or lever of the second moment) about the A_S axis and in equation (16) R_F is the lever of the third moment about the A_S axis. There are six unknowns: A_F , B_F , D_F , A_F , A_F . All other quantities can be determined from the geometry of the forebody.

For the aftbody there are five more equations similar to (12), (13), (14), (15), (16), but with coefficients A, B, C, D changed to E, F, G, H respectively and subscript F replaced by A. There the six unknowns are E, F, G, H, $\&V_A$, V_{SA} .

5b. <u>Combined Forebody and Aftbody</u>

Figure 5 applies and the two equations for the total section area curve are again equations (7) and (8). With equations (12), (13), (14), (15), (16) for the forebody, five similar equations for the aftbody, and equations (7) and (8) for

the total section area curve, we have a system of twelve equations in twelve unknowns. These equations are written in matrix form in Figure 7. The twelve unknowns are contained in the column vector at the right. The matrix and the column vector at the left contain all known quantities. Using Gaussian elimination for the solution the coefficients A, B, C, D and E, F, G, H are calculated and so the longitudinal shifts in the forebody are:

$$(17) \quad \delta x_{\mathfrak{p}} = Ax^3 + Bx^2 + Cx + D$$

and the longitudinal shifts in the aftbody are

(18)
$$8x_{\Lambda} = Ex^3 + Fx^2 + Gx + H$$

When points on the parent section area curve are shifted longitudinally according to equations (17) and (18), the resulting section area curve will have the desired prismatic coefficient, longitudinal center of buoyancy, extent of parallel midbody, slope of entrance, and slope of run. When stations in the offsets are shifted longitudinally according to equations (17) and (18), a derived hull fon will result which has these characteristics. A new hull will have been generated from a parent hull using section area curve variation.

FIGURE 7. Twelve Linear Simultaneous Equations for Cubic Longitudinal Shifts

6. CONCLUSIONS

Some typical computer methods for generating new ship lines were first briefly discussed. Then the lines distortion approach of section area curve variation was presented in detail. A systematic mathematical approach to section area curve variation using matrices was developed which gives a closed form solution and simplifies changing the boundary conditions. The derivation of a system of twelve linear simultaneous equations for cubic longitudinal shifts demonstrates how two more boundary conditions are easily added to the original system of ten equations. Several examples with numeric and graphic results from a computer program developed at the Maritime Administration are presented. The graphic results demonstrate that the derived section area curves look reasonable and the numeric results show that the derived curve has the desired form parameters.

Development is underway to add calculations and plots of the non-dimensional curvature of both parent and derived section area curves to the computer program. This would show how section area curve variation affects the curvatures on the parent section area curve. Additionally, it would be interesting to see the results of using section area curve variation on a hull which was faired by a program like HULDEF, since the program has not been tested on a construction design. In any case the method presented should be adequate for generating new lines for preliminary design, with the restriction that changes be moderate, i.e., up to 10% change in prismatic coefficient and about 2% change in longitudinal center of buoyancy.
